Acute coronary syndromes (ACS) are among the most severe complications of atherosclerosis, and the majority, although not all, take place due to atheromatous plaque rupture and subsequent thrombosis. The genesis of the atheroma is triggered by the appearance of a discontinuity in the endothelial layer, followed by an array of complex mechanical, biochemical, and biological mechanisms that will eventually lead to plaque formation. The formed atherosclerotic plaque will undergo several pathophysiological changes, including the excessive accumulation of oxidized LDL-cholesterol, enhanced local inflammation, smooth muscle cell proliferation, and extracellular matrix degradation, which will eventually lead to its progression and destabilization.
In an attempt to define the complications related to atherosclerotic plaques and to find the pathophysiological mechanism of acute coronary syndromes, the concept of “vulnerable plaque” was developed. The definition of the vulnerable coronary plaque comprises an increased propensity towards rupture, erosion, and thrombosis.

A vulnerable plaque is described as having a thin fibrous cap and a large necrotic lipid core that initially causes an eccentric vascular remodeling (positive remodeling) followed by luminal stenosis and impaired distal blood flow. Other features of unstable coronary lesions include an increased local inflammation, extracellular matrix degradation, neo-vessel formation within the plaque with subsequent hemorrhage, as well as calcium formation in the form of spotty calcifications.

Even though the most common fate of an unstable plaque is to rupture, a significant percentage of acute coronary syndromes were shown to be caused by coronary plaque erosion. Lesions that suffer erosions seem to not show the established characteristics of a vulnerable plaque, usually presenting a thick cap, decreased necrotic cores and lower inflammation degree. Thus came the idea that a vulnerable plaque is not as much prone to rupture, but more prone to causing an acute event.

**SHEAR STRESS AND VULNERABLE PLAQUES**

The complex pathophysiological mechanism of atherosclerosis includes, besides progressive endothelial injury, local inflammation, and vascular remodeling, also hemodynamic alterations. It was shown that there is an increased occurrence of coronary plaques in vascular regions with high shear stress, such as bifurcations or near vascular curvatures. Also, the protrusion of the atheroma in the vessel lumen causes a shift from a normal, laminar flow, with evenly distributed transverse and shear stress, to a turbulent flow. Coronary shear stress (CSS) has been shown to influence the progression of coronary plaques by causing structural and functional changes in the endothelium, enzymatic changes, release of bioactive markers, and gene transcription. Low shear stress (LSS) leads to misalignment of the endothelial cells, increased permeability to circulating lipid molecules and inflammatory cytokines, as well as high expression of adhesion molecules, growth factors, and high reactive oxygen species. In the context of increased systemic cardiovascular risk factors, the dysfunctional endothelium and increased inflammatory status augment the process of plaque growth and cause additional alterations of the endothelial shear stress. High shear stress exposure presents a protective effect on healthy vessels, but if a stenotic lesion is present, it indorses plaque vulnerability.

High shear stress contributes to plaque destabilization by increased nitric oxide expression and extracellular matrix degradation by stimulating the expression of matrix metalloproteases, increased production of proteolytic enzymes, and apoptosis. Furthermore, an increased CSS can stimulate plaque denudation and erosion, which, if associated with an enhanced blood thrombogenicity, lead to acute vessel occlusion and the occurrence of an ACS. Shear stress distribution across coronary stenotic lesions appears to be low in the distal region of the plaque, whilst a high stress is mainly present in the proximal part. In order to maintain the physiological shear stress, vascular remodeling occurs as an adaptive process, thus a high CSS stimulates an outward remodeling, while a low CSS exposure will lead to an inward remodeling with vessel narrowing.

**METHODS FOR THE ASSESSMENT OF VULNERABLE PLAQUE CHARACTERISTICS**

There are several established methods for the assessment of biomarkers characteristic for plaque instability, acquired with both invasive and noninvasive techniques. The invasive methods include intravascular ultrasound (IVUS) with its different variations (virtual histology IVUS, iMAP IVUS, and integrated backscatter IVUS), which can assess with high accuracy the total plaque burden, necrotic core, neo-vessel formation, calcifications, as well as the vessel remodeling percentage. Optical coherence tomography (OCT), which uses near-infrared light for image acquisition, allows evaluation of the fibrous cap, collagen amount, neoangiogenesis, plaque rupture and thrombus formation; its variant, micro-OCT, is able to offer a histological level of accuracy in the process of plaque component visualization. Other invasive methods for evaluating unstable coronary plaques include invasive coronary thermography (which measures plaque temperature), near-infrared spectroscopy (NIRS – better visualization of necrotic cores), and also combinations of the above-mentioned methods. Coronary computed tomography angiography (CCTA) has emerged as the most used technique for noninvasive plaque evaluation, being able to identify several CT biomarkers for plaque instability. The advantages of this method are that it is noninvasive, it allows the visualization of the complete coronary tree, and it also holds the ability to analyze both the vascular lumen and the wall. Moreover, recent developments have led to an increase in image quality and resolution, by using multiple slice scans with ECG-gat-
ed protocols that allow imaging acquisition in a single heartbeat, during diastole, thus eliminating motion artifacts.\textsuperscript{54,55} CCTA displays an increased rule-out capacity for lesion identification and quantification, and studies have shown that its detection accuracy is comparable to invasive methods (IVUS and OCT), even if it does not hold the ability for fibrous cap identification.\textsuperscript{21,53,54} Major advantages of the latter are: 3D data collection and visualization, as well as information on arterial calcification and vascular distortion.\textsuperscript{55} The markers for plaque vulnerability that are identified by CCTA are the presence and size of the necrotic core (which appears as a hypodense area within the plaque),\textsuperscript{56,57} low attenuation plaques,\textsuperscript{58} positive remodeling (and calculation of the remodeling index),\textsuperscript{59} the presence of the napkin-ring sign,\textsuperscript{60} and microcalcification within the plaque (referred to as spotty calcifications).\textsuperscript{61,62} CCTA is also able to evaluate the overall degree of calcification of the coronary tree by using the coronary artery calcium score, which has been shown to have a high predictive capacity for major adverse cardiovascular events, being combined with traditional cardiovascular risk factors (c–statistic of 0.93).\textsuperscript{63}

Other applications of CCTA include the noninvasive assessment of coronary blood flow and the function significance of coronary lesions, with the use of CT-based fractional flow reserve (CT–FFR),\textsuperscript{64,65} as well as the transluminal attenuation gradient through a coronary stenosis.\textsuperscript{66} Nevertheless, CCTA has a great potential of being integrated into computational simulation models for coronary flow and fluid dynamics, which will allow the analysis of plaque conduct in physiological and pathological circumstances.\textsuperscript{21} Computational models are the sole methods that are currently able to integrate both the external (hemodynamic) and internal (characteristics of plaque) markers for instability in order to achieve a global understanding of the conditions that lead to plaque erosion and rupture with the subsequent occurrence of an acute coronary syndrome.\textsuperscript{21,67,68} One of the most important drawbacks of computational simulation models is the increased time needed for image reconstruction, but with recent developments, the time has been reduced from weeks\textsuperscript{69} to less than two hours,\textsuperscript{70} which make it possible for computational plaque analysis to be performed as a part of a living vessel.\textsuperscript{21}

Accurately identifying coronary plaques is challenging, especially when using noninvasive methods such as CCTA. The problems encountered in the CT analysis of coronary plaques include the presence of non-calcified lesions, small sized vessels, as well as motion artifacts that can be diminished by using ECG–gated CT protocols, multiplanar image acquisition and vessel segmentation, and vascular tree reconstruction techniques.\textsuperscript{71,72}

CORONARY TREE SEGMENTATION

The segmentation of vascular trees is a widely researched topic. The literature includes several studies that follow the data–driven approach, namely they treat the notion of the vascular tree in a general way, as a set of interconnected tubular structures, with possible bifurcations and stenoses, but without using any anatomical information. These studies usually concentrate on image quality enhancement for vessel recognition,\textsuperscript{73} accurate detection of bifurcations and branches,\textsuperscript{74–77} extraction of the most probable centerline,\textsuperscript{78,79} vessel diameter estimation,\textsuperscript{79,80} and the identification of odd structures.\textsuperscript{81,82} Although they are very important in the development of useful medical data processing techniques, these general studies do not take into consideration any anatomical information of a chosen vessel tree.

On the other hand, the literature also includes studies on arterial tree segmentation procedures designed for and tested on specific arterial networks. The major part of such studies focuses on the coronary artery tree (CAT),\textsuperscript{83,84} but there are several works developed for the pulmonary arteries,\textsuperscript{85–88} cerebral arteries,\textsuperscript{89} the carotid artery,\textsuperscript{90} and vessels of the retina.\textsuperscript{91,92}

SEGMENTATION METHODS FOR CORONARY ARTERIES IN ACUTE CORONARY SYNDROMES

DATA-DRIVEN SEGMENTATION METHODS

Cimen \textit{et al.}\textsuperscript{93,94} proposed a method to reconstruct 3D views of the CAT from 2D X-ray images based on a probabilistic mixture model and maximum likelihood estimation. Hu \textit{et al.}\textsuperscript{95} proposed a two–step solution for the same problem: in a first stage they extracted artery tree boundaries via minimal path segmentation, then applied maximum a posteriori (MAP) reconstruction using L0–norm and L1–norm priors. Fallavollita and Cheriet\textsuperscript{96} provided a 3D coronary artery reconstruction technique from reduced number of 2D X-ray fluoroscopy images that follows the non–rigid movement of arteries, significantly decreasing the reconstruction error.

Gülsün \textit{et al.}\textsuperscript{97} employed computed flow fields to eliminate shortcuts in automatically detected blood vessel centerlines, and Kitamura \textit{et al.}\textsuperscript{98} used a Markov Random Field framework and AdaBoost classifier for vascular structure segmentation, assisted by topological constraints in order...
to avoid inconsistency in the vascular network. Dufour et al.\textsuperscript{99} combined the Hessian matrix approach and the gray-level hit-or-miss transform to obtain vessel candidate pixels in CTA data, which were later classified using decision trees. Krissian et al.\textsuperscript{100} established a geodesic level set framework to semi-automatically detect the aorta with its main bifurcations and branches, extract the centerline of each branch, and identify the presence of aortic dissection. Zhou et al.\textsuperscript{83} introduced the notion of multiscale coronary response, a robust method designed to find coronary arteries via combining 3D multiscale filtering, analysis of the eigenvalues of the Hessian matrices, and expectation maximization (EM) estimation techniques. They also employed a 3D dynamic balloon tracking method to extract complete artery trees. Shang et al.\textsuperscript{101} defined a vector field based on the eigenanalysis of the Hessian matrix and used it to assist a 3D active contour model in the detection of vascular structures.

MODEL-DRIVEN SEGMENTATION METHODS

The most part of recently developed CAT segmentation methods follows the model-based or the model-driven approach, through involving anatomical models or atlases to improve the segmentation accuracy. Model-based methods start with extracting relevant information from the recorded image data, but in a later processing phase they match the extracted information with predefined atlases or models.

Shin et al.\textsuperscript{102} employed a manually annotated 2D fluoroscopic X-ray image as reference and proposed a technique to extract coronary vessels from further images via vessel correspondence optimization. Liu et al.\textsuperscript{103,104} proposed a model-guided centerline extraction method based on ostia detection via directional minimal paths and validated it on the three main branches of the CAT in CTA image data. Sun et al.\textsuperscript{105} deployed a previously recorded 3D vessel model of the same patient to track the position of various branches within 2D X-ray angiograms, using exploratory shortest paths within the graph model of the vessels. Medrano-Garcia et al.\textsuperscript{106} built a coronary artery atlas using 122 CTA records of zero calcium score, providing a comprehensive and accurate assessment of the anatomy, including 3D size, geometry, and shape descriptors.

In model-driven methods the identification of vessels and centerlines relies on a priori defined cardiovascular models. For example, the method proposed by Zheng et al.\textsuperscript{107} automatically segments the heart chambers and then uses an anatomical model to automatically track various branches of the CAT. The model helps the centerline tracing procedure to avoid early termination at severe occlusions and to generate anatomically consistent centerlines.

THE DESIGN OF THE SEGMENTATION METHOD

The main steps of the proposed solution include preprocessing, seed extraction for region growing, data-driven segmentation via robust fuzzy region growing, centerline extraction, model-based validation and vessel identification, and post-processing.\textsuperscript{108–112}

THE USE OF CT IN EMERGENCY SETTINGS AND FOR ACUTE CORONARY SYNDROMES

The use of CCTA has been shown to be feasible and useful for patients who present in the emergency department for acute chest pain, but have equivocal laboratory and electrocardiographic (ECG) modifications. The Rule Out Myocardial Infarction/Ischemia Using Computer Assisted Tomography (ROMICAT-I) trial included 368 patients with acute chest pain, normal initial troponin values, and no signs of myocardial ischemia on the initial ECG.\textsuperscript{113} The results showed that emergency CCTA had a high negative predictive value (100% in the absence of CAD, 98% in the presence of significant coronary lesions) in ruling out an acute coronary syndrome.\textsuperscript{113}

Another trial on the use of CCTA in the emergency department (ED), which included 1,000 patients with acute chest pain, showed that in comparison to a traditional diagnostic procedure (invasive coronary angiography), the hospitalization index was decreased by 7.6 h (period of stay in the emergency department), and a significantly larger number of patients had been discharged straight from the ED (47% for CCTA vs. 12% for the invasive approach).\textsuperscript{114}

As it allows rule-out of acute pulmonary embolism, aortic dissection, and acute coronary syndromes, depiction of the complete coronary anatomy, illustration of the coronary vessel lumen, identification of vulnerable plaque features, as well as the coronary artery calcium score, CCTA is a valuable method for emergency triage and patient management, for the decision-making process and prognosis assessment of patients with coronary artery disease, all in a noninvasive stand-alone procedure.\textsuperscript{55,115–117} The noninvasive visualization of plaque characteristics and severity of the coronary artery disease in patients with non–ST elevation acute coronary syndromes at baseline, was shown to predict recurrent adverse events.\textsuperscript{118}
CONCLUSIONS
Computational methods can be easily applied in the vascular system for coronary artery tree segmentation using CTA image volumes. This interdisciplinary approach can provide a solid background for a complex assessment of the coronary tree, especially in settings when estimation of the degree of plaque vulnerability can be crucial for the future evolution of the patients.
